Abstract. AgeCoin (AGE) is a cryptocurrency secured by a consensus mechanism known as Proof-of-Age: a validation model that assigns voting weight to validators based on the duration and consistency of their honest participation in the network, rather than on computational power (as in Proof-of-Work) or solely on the amount of capital staked (as in most Proof-of-Stake systems). Consequently, the cost of gaining control over the network is determined not by who possesses the most hardware or capital, but by who is willing to build a consistent track record of honesty over time—a resource that cannot be purchased instantly. This document outlines the problem AgeCoin aims to address, the mechanics of Proof-of-Age, its incentive structure and tokenomics, as well as its limitations and risks.

1. Introduction

Two consensus approaches currently dominate the crypto landscape. Proof-of-Work (as seen in Bitcoin) has proven secure for over a decade but demands immense energy consumption, as its security relies on a race for computational power. Proof-of-Stake reduces this energy consumption but tends to hand network control to those with the most capital—whoever holds the most coins wields the most power over the network from the very moment of purchase.

AgeCoin proposes a third path. Instead of asking "who possesses the most computational power?" or "who has the most capital?", Proof-of-Age asks: "who has proven themselves honest and consistent over the longest period?" Time is the only resource that

cannot be accelerated, bought in bulk, or rented overnight. By placing time and reputation at the core of validation weighting, AgeCoin aims to create a network that remains as energy-efficient as Proof-of-Stake, yet is more resilient against domination by large capital holders who arrive seeking immediate control.

2. The Issue: Instant Power vs. Established Trust

In purely capital-based systems, an entity with substantial funds can—in theory—acquire majority validation power in a short time and immediately influence the network without ever having demonstrated good intentions. In systems based solely on computational work, power gravitates toward parties with the cheapest access to electricity and the latest hardware—factors that do not necessarily align with the long-term interests of the user community.

AgeCoin is founded on the premise that a healthy payment network should be safeguarded by parties that have demonstrated long-term commitment to the network itself, rather than merely by those who can amass resources the fastest. The challenge lies in designing a mechanism capable of objectively measuring this "long-term commitment"—one that is verifiable by anyone and cannot be faked or artificially accelerated.

3. Proof-of-Age: Basic Concepts

Proof-of-Age introduces a metric known as the "Age Score" for each validator. The Age Score begins at zero when a node first joins as a validator and grows incrementally as long as the node:

1. Maintains a certain amount of AGE locked as collateral,
2. Remains consistently online and responsive to the network,
3. Correctly validates transactions and blocks in accordance with protocol rules, and

4. Is never proven to have committed a violation resulting in slashing (see Section 8).

Conceptually, the Age Score can be described as follows: The function is designed so that growth slows over time (rather than increasing linearly without limit); this ensures that new validators have a realistic path to building influence, while long-standing validators do not automatically dominate indefinitely simply by virtue of having joined earlier. The Age Score also decays (decreases) if a node is frequently offline, often fails to validate on time, or ceases participation—reputation must be continuously maintained, not merely achieved once.

With this structure, attempts to fraudulently seize control of the network (such as by creating multiple fake validators or launching a Sybil attack) become costly not only in terms of capital but also time: every fake validator must undergo the same lengthy period of honest participation before its vote carries any weight, and that period cannot be shortened by simply adding more funds or hardware.

4. Block Proposer Selection and Finality

In each block creation round, a validator is selected as the block proposer via weighted random selection. Each validator's weight is proportional to their Age Score, subject to a cap that prevents any single validator from dominating the selection process, even if they possess an exceptionally high Age Score. The selected validator assembles validated transactions into a candidate block and broadcasts it to the network.

The block is subsequently finalized through a voting process involving the set of validators with the highest Age Scores for that round. A block is deemed final once it receives approval signatures representing more than two-thirds of the total Age Score weight participating in the round. The target inter-block time is

approximately 3 seconds, allowing transactions to achieve practical finality in seconds rather than minutes.

The fundamental security assumption of Proof-of-Age is that, provided the majority of the network's aggregate Age Score is controlled by honest validators, the chain produced by this honest majority will always be the most trusted chain and the hardest for dishonest actors to rival; this is because challenging it requires legitimately building up an equivalent Age Score—a process that demands time, not merely funds.

5. Network and Propagation

Like typical peer-to-peer networks, AgeCoin nodes are loosely connected and propagate transactions and blocks on a best-effort basis. New nodes can join at any time by downloading the current blockchain, and nodes that have been disconnected can catch up by requesting missed blocks once they come back online. The network does not require a central authority to operate; each node can independently verify the validity of a block based on the validator's signature and the Age Score history publicly recorded on the chain.

6. Incentives and Reward Schemes

Validators who successfully propose and finalize blocks receive two types of rewards:

Block rewards, consisting of newly issued AGE tokens distributed according to a predetermined emission schedule that gradually decreases over time—mirroring the scarcity principle where an asset becomes more valuable as the rate of new supply slows.

Transaction fees, representing the difference between input and output values for each transaction included in a block; these will serve as the primary incentive once new block emissions approach zero.

Since a validator's validation weight depends on an Age Score built up over years, engaging in fraudulent behavior—which risks having

that Age Score "slashed" (partially or fully forfeited)—would result in losses far outweighing any potential short-term gains from the fraud. Long-term incentives are designed to consistently outweigh the incentives for cheating.

8. Tokenomics

The total supply of AGE is permanently capped at 1,000,000,000AGE, allocated as follows:

Allocation	Percentage	Description
Developer Rewards	10%	Distributed gradually to validators as an incentive for maintaining the network
Community & Ecosystem	25%	Developer grants, partnerships, and community growth programs
Public Sale	50%	Sold to the public to fund development and initial liquidity
Team & Advisors	15%	Locked with a 24-month vesting schedule

9. Governance Community

Every AGE holder can propose and vote on protocol changes onchain, with voting weight factoring in both the amount of AGE held and the Age Score for those acting as validators. The objective is to avoid decisions made behind closed doors by a select few and to ensure the network's development trajectory reflects the community's long-term interests, rather than merely the short-term interests of a handful of major coin holders.

10. Privacy

Like most public blockchain networks, all AgeCoin transactions are recorded publicly and are visible to anyone. What is not directly exposed is the real-world identity behind each address (public key).

To maintain a reasonable level of privacy, users are advised to use a new key pair for each transaction, making it more difficult to link transaction history to a single identity. It should be noted that transactions involving multiple input addresses simultaneously can naturally indicate that those addresses are owned by the same party.

11. Roadmap

Stage 1 — Coin Information: Information regarding our coin launch will be announced via X (@AgeCoin_xyz).

Stage 2 — Security Audit: Our development team will continuously conduct research on bugs.

Stage 3 — Coin Launch: AgeCoin will be officially launched on the Solana network.

Stage 4 — On-Chain Governance: The voting module is open, allowing every AGE holder to determine the future direction of development.

12. Risks and Limitations

This document outlines the proposed design rather than guaranteeing specific outcomes. Prospective users and validators should be aware of the following risks:

The Age Score mechanism has not been tested at production scale over a period of years, unlike conventional Proof-of-Work or Proof-of-Stake systems.

The value of AGE, like crypto assets in general, can be highly volatile and may experience significant depreciation.

Vulnerabilities in software implementation (such as smart contract bugs or consensus errors) remain possible, even after audits have been conducted.

Regulatory changes across various jurisdictions could affect the legality or accessibility of AgeCoin in specific regions.

13. Conclusion

AgeCoin proposes a consensus approach that positions time and reputation as the primary resources for network security, aiming to combine Proof-of-Stake-style energy efficiency with resilience against instant capital dominance. Through the Age Score, the most trusted validators are those who have consistently proven themselves over time—rather than those who simply possess the most funds or hardware on day one. This design remains a proposal that will undergo further refinement through testnet phases, audits, and community feedback prior to launch.
